## SCRS/02/068

# A Preliminary Assessment of Atlantic White Marlin (Tetrapturus albidus) Using a State-Space Implementation of an Age-structured Production Model 

Clay E. Porch

This paper illustrates the application of a state-space age-structured production model to Atlantic white marlin. An age-structured approach was applied to accommodate the possibility that the vulnerability of white marlin to the various fisheries changes with age. A state-space representation was employed to facilitate parameter estimation by accommodating Bayesian priors and inter-annual changes in parameters such as the catchability coefficients. The latter capability may prove especially useful inasmuch as the catchabilities appear to have increased during the early year of several of the CPUE time series. However, initial runs of the model in an attempt to duplicate the ASPIC and FISHLAB runs made by the 2000 SCRS indicate that the steepness parameter of the spawner-recruit relationship and the age at $50 \%$ vulnerability cannot be estimated reliably. This implies that an informative priors are required for these parameters before additional complexities are examined. The steepness parameter in particular has a strong influence on the model perception of the level of fishing mortality that can be sustained over the long term.

This paper reports on the application of a state-space implementation of an age-structured production model (ASPM) to Atlantic white marlin. An age-structured approach was applied to allow the fecundity and vulnerability of white marlin to change with age. A state-space representation was employed to facilitate parameter estimation by accommodating Bayesian priors and inter-annual changes in parameters such as the catchability coefficients and recruitment. The specific examples presented are purely illustrative and are not intended to form the basis for generating management advice. It is hoped, however, that discussions during the upcoming SCRS working group meeting will lead to a more useful model.

## Deterministic population dynamics

The abundance of each age class is computed at monthly intervals according to the formula

$$
\begin{equation*}
N_{a, y, m+1}=N_{a, y, m} e^{-M_{a} \delta}-\sum_{\mathrm{i}} C_{a, y, m, i} \tag{1}
\end{equation*}
$$

where $N_{a, y, m}$ is the number of fish in age class $a$ at the beginning of month $m$ in year $y, C_{a, y, m, i}$ is the catch in numbers of fleet $i, M$ is the natural mortality rate coefficient and $\delta$ is the duration of the time step in years (= $1 / 12$ ).

The abundance at the beginning of the first month is modeled as

$$
N_{a, y+1,1}= \begin{cases}\frac{4 h S_{y-\alpha}}{\theta_{0}(1-h)+S_{y-\alpha}(5 h-1) / R_{0}} & a=\alpha  \tag{2}\\ N_{a-1, y, 13} & \alpha<a<A \\ N_{A-1, y, 13}+N_{A, y, 13} & a=A\end{cases}
$$

where the subscript 13 denotes the end of the $12^{\text {th }}$ month (beginning of the next year). Note that the initial abundance of the youngest age class $(\alpha)$ is modeled by the Beverton and Holt (1957) function of spawning biomass $(S)$ recast in terms of virgin recruitment $R_{0}$, virgin spawning biomass per recruit $\theta_{0}$, and steepness $h$. Steepness is defined as the recruitment when $S$ is $20 \%$ of the virgin level relative to the recruitment at the virgin level (where $0.2<h \leq 1$ ).

Spawning biomass $S$ is expressed

$$
\begin{equation*}
S_{y}=\sum_{a} p_{a} w_{a} N_{a, y, t} \tag{3}
\end{equation*}
$$

where $p$ is the proportion of each age class that is sexually mature and $w$ is the average weight of mature individuals during the month $t$ when spawning takes place. Similarly, the equilibrium spawning biomass per recruit for a given vector of fishing mortality rates at age $(F)$ is computed

$$
\begin{equation*}
\theta_{F}=\sum_{a=\alpha}^{A-1} p_{a} w_{a} e^{-\left(Z_{a} \tau+\sum_{j=\alpha}^{a-1} Z_{j}\right)}+\frac{p_{A} w_{A}}{1-e^{-Z_{A}}} e^{-\left(Z_{A} \tau+\sum_{j=\alpha}^{A-1} Z_{j}\right)} \tag{4}
\end{equation*}
$$

where $Z_{a}=M_{a}+F_{a}, \tau$ is the fraction of the year elapsed at the time of spawning ( $=t / 12$ ). The virgin level $\left(\theta_{0}\right)$, which is used in equation (2) above, is obtained by setting $F_{a}=0$.

The age structure of the population at the start of the first year in the analysis $(y=1)$ is assumed to have reached an equilibrium at some historical level of fishing mortality $F_{a}=\phi_{a}$. In that case the expected spawning biomass per recruit is computed by (4). Rearranging the spawner-recruit relationship then gives a value for the corresponding equilibrium recruitment

$$
\begin{equation*}
R_{\phi}=R_{0} \frac{4 h \theta_{\phi}-(1-h) \theta_{0}}{\theta_{\phi}(5 h-1)} \tag{5}
\end{equation*}
$$

Thus, the initial (equilibrium) age structure is

$$
N_{a, y, 1}= \begin{cases}R_{\phi} & a=\alpha, y<\alpha+1  \tag{6}\\ R_{\phi}^{-\sum_{j=\alpha}^{a-1}\left(M_{a}+\phi_{a}\right)} & \alpha<a<A, y=1 \\ \frac{R_{\phi} e^{-\sum_{j=\alpha}^{A-1}\left(M_{a}+\phi_{a}\right)}}{1-e^{-\left(M_{A}+\phi_{A}\right)}} & a=A, y=1\end{cases}
$$

The assumption that the vector $\phi$ has been constant for an extended period may be unrealistic in some applications, but nevertheless affords more flexibility than the usual assumption that the initial population is at virgin levels $(\phi=0)$. However, it is important to realize that the use of nonzero $\phi$ requires

$$
\begin{equation*}
h>\left(1+4 \frac{\theta_{\phi}}{\theta_{0}}\right)^{-1} . \tag{7}
\end{equation*}
$$

In essence, large values of $\phi$, which lead to small values of $\theta$, cannot be sustained unless $h$ is close to 1 .

The monthly catch of the $i$ 'th fishing entity (fleet) is computed as though it occurred as a pulse at the end of the month, after natural mortality and after the catch of fleets 1 through $i-1$ :

$$
\begin{equation*}
C_{a, y, m, i}=F_{a, y, i}\left(N_{a, y, m} e^{-M_{a} \delta}-\sum_{k=1}^{i-1} C_{a, y, m, k}\right) \frac{\delta}{\tau_{i}} \tag{8}
\end{equation*}
$$

where $\tau_{i}$ is the duration of the fishing season. The corresponding catch in weight is computed by multiplying (8) by $w_{a, y}$. Note that this formulation is only approximate when the fleets actually fish simultaneously rather than sequentially, but with monthly time steps the error is negligible.

The fishing mortality rate $F$ is separated into components representing the age-specific
relative-vulnerability $v$, annual effort expended $f$, and a catchability coefficient $q$ :

$$
\begin{equation*}
F_{a, y, i}=q_{y, i} f_{y, i} v_{a, i} \tag{9}
\end{equation*}
$$

The catchability coefficient $q$ is the fraction of the most vulnerable age class that is taken per unit effort. Note that $q$ may be allowed to vary from year to year rather than remain fixed in order to accommodate variations in the efficiency of the fishing process (see discussion of process errors below). The relative vulnerability coefficients implicitly include factors such as gear selectivity, size limit regulations, and the fraction of the stock exposed to the fishery. They are modeled by a logistic selection curve with the dispersion coefficient v set to 0.2 (equivalent to knife-edge selection):

$$
\begin{equation*}
v_{i, a}=\frac{1}{1+e^{-\left(a-a_{50, i}\right) / d_{i}}} \tag{10}
\end{equation*}
$$

where $a_{50, i}$ is the age of $50 \%$ relative vulnerability for fleet $i$ and $d_{i}$ is the dispersion coefficient controlling the slope of the curve at $a_{50, i}$ (a value of 0.2 or less effectively implie knife-edge selection).

Time series of catch per unit effort (CPUE) or fishery-independent abundance surveys are modeled as though the observations were made just before the catch of the fleet with the corresponding index $i$ :

$$
\begin{equation*}
I_{y, m, i}=q_{y, i} \sum_{a} v_{a, i}\left(N_{a, y, m} e^{-M_{a, y} \delta}-\sum_{k=1}^{i-1} C_{a, y, m, k}\right) \frac{\delta}{\tau_{i}} \tag{11}
\end{equation*}
$$

As for catch, the corresponding CPUE in weight is computed by multiplying (11) by $w_{a, y}$.
The average weight of was computed as a power function of length, which in turn was computed as a von Betalanffy function of age:

The average weight for plus-group, however, depends on its age composition. To the extent that growth after the plus-age is approximately linear, the average weight may be caluculated from the average age of the plus-group. Initially, it is assumed that the age composition of the plus-group is in equilibrium consistent with equation (6), in which case the average age at the beginning of the year is

$$
\begin{equation*}
\bar{a}_{A, 1}=A+\frac{e^{-\left(M_{A}+\phi_{A}\right)}}{\left(1-e^{-\left(M_{A}+\phi_{A}\right)}\right)} \tag{13}
\end{equation*}
$$

Subsequently, the age of the plus-group is updated as

$$
\begin{equation*}
\bar{a}_{A, y+1}=\frac{A N_{A-1, y, 13}+\left(\bar{a}_{A, y}+1\right) N_{A, y, 13}}{N_{A, y+1,1}} . \tag{14}
\end{equation*}
$$

## State space implementation

Process errors in the state variables and observation errors in the data variables are accommodated using the first-order autoregressive (AR1) model

$$
\begin{align*}
& g_{t+1}=\mathrm{E}\left[g_{t+1}\right] e^{\varepsilon_{t+1}}  \tag{15}\\
& \varepsilon_{t+1}=\rho \varepsilon_{t}+\eta_{t+1}
\end{align*}
$$

where $g$ represents any given state or observation variable, $\eta$ is a normal-distributed random error with mean 0 and standard deviation $\sigma_{\mathrm{g}}$, and $\mathrm{E}[g]$ denotes the value of $g$ given by the deterministic components of the process or observation dynamics (equations 1-14). In the case of data, the $g_{t}$ in (15) correspond to observed quantities, but in the case of states the $g_{t}$ are unobserved and must be estimated along with the parameter vector.

For stability reasons, it is assumed that $\varepsilon_{0}=0$, leading to the negative log-density

$$
\begin{align*}
-\log \mathrm{P}(g \mid \Theta, \mathbf{X})= & \frac{1}{2 \sigma_{g}^{2}}\left[\left(\ln g_{1}-\ln \mathrm{E}\left[g_{1}\right]\right)^{2}+\sum_{t=1}^{N-1}\left(\ln g_{t+1}-\ln \mathrm{E}\left[g_{t+1}\right]-\rho \ln g_{t}+\rho \ln \mathrm{E}\left[g_{t}\right]\right)^{2}\right],  \tag{16}\\
& +N \log \sigma_{g}
\end{align*}
$$

where $\rho_{g}$ is the correlation coefficient and $\sigma_{g}^{2}$ is the variance of $\log _{e}(\eta)$. In the present model, the variances of the process and observation errors are parameterized as multiples of an overall coefficient of variation parameter CV , i.e., $\sigma_{g}{ }^{2}=\log _{e}\left[\left(\lambda_{g} C \mathrm{~V}\right)^{2}+1\right]$. Note that the 'random walk' model of Fournier et al. (1998) is merely a special case of (15) with $\rho=1$ and $\mathrm{E}\left[g_{t}\right]=g_{0}$ (a timeinvariant parameter).

The model was implemented using the nonlinear optimization package AD Model Builder (Otter Research Ltd., 2000), which provides facilities for estimating the mode and shape of posterior distributions formed by (16) and the negative logarithms of the priors.

## Application to white marlin

Two runs were made that were essentially equivalent to the SCRS (2001) base-case runs with (i) a single composite CPUE series, and (ii) eight separate CPUE series. The catch and CPUE observations are assumed by the model to be unbiased, but imprecise. The annual catches fromeach fleet were assumed to be equally uncertain with constant coefficient of variation $C V$ estimated by the model. The annual CPUE values for each fleet were assumed to be less certain than the catches, and were assigned coefficients of variation that were twice as large as the values estimated for the catch $(2 C V)$. In the case of the composite model, the annual CPUE values were also weighted by the standard errors (Ortiz et al., 20) scaled by the minimum value. The fleet-specific CPUE series were given equal weight.

Effort was allowed to vary from year to year essentially as a free parameter by allowing a relatively large process error $(10 C V)$ and moderate correlation ( $\rho=0.5$ ). No process error was allowed for the other state variables.

The catchability coefficients $q$ were estimated as time-independent constants in runs (i) and (ii). However, a third run was made with the composite series where the catchability coefficient was allowed to vary annually as a random walk process $(\rho=.99)$ with coefficient of variation 2 CV .

There was little basis upon which to formulate the priors for the estimated parameters, therefore I used uniform priors defined over a plausible range of values (see Table 3). The only exceptions were the natural mortality $M$ and growth coefficients, which were held constant inasmuch as they are notoriously difficult to estimate from catch and CPUE time series alone. The value of $M$ was set to 0.1 , a low value reflecting the longevity of white marlin and related species (see SCRS 2001). The relationship between weight and length was modeled as estimated by Prager et al. (1995). The relationship between age and length for white marlin is poorly known, therefore von Bertalanffy growth coefficients were assumed to be approximately the same as for sailfish (Istiophorus platypterus) from the Gulf of California (Alvarado and Felix, 1998). This strategy, while inexact, should nevertheless be superior to assuming all age classes weigh the same as lumped-biomass production models do. Fish above age 9 were lumped together as a "plus" group.

## RESULTS

## Composite series

The constant and random-walk $q$ models both fitthe catch data rather well (Figure 1) inasmuch as the catch data were assumed to be about twice as precise as the CPUE information. The fit to the CPUE data by the constant $q$ model was very similar to the fit provided by the equivalent ASPIC and FISHLAB logistic production models (SCRS 2001). The fit by the random-walk $q$ model was much better as it could partly reconcile the simultaneous increase in catch and CPUE. The appraisals of stock status from both models similar to those produced by ASPIC and FISHLAB. All suggest that the spawning biomass has declined well below the level associated with MSY and that the fishing mortality rate has increased to well above $F_{M S Y}$ (see Figures 2-4, Table 4).

Most of the parameters appeared well determined, their estimates having CV's under $40 \%$. However, the estimate for $h$ tended toward the upper boundary of 0.95 and the estimate for $a_{50}$ tended to the boundary of 3.0 (Figure 4). Moreover, minor changes in model structure or the order in which parameters were estimated could cause the estimate of $h$ to swing to the lower boundary (as it does for the fleet-specific model below).

## Fleet-specific series

The model fit to the catch data (Figure 5) is generally good except for a few years during the early part of the Japanese longline series. The fits to the CPUE data (Figure 6) were similar to the fits provided by the equivalent FISHLAB logistic production model (SCRS 2001). As was true for the composite runs above, the fleet-specific ASPM appraisal of stock status was similar to that of the SCRS FISHLAB model. Both models suggest the spawning biomass has declined below the level associated with MSY and that the fishing mortality rate has increased above $F_{M S Y}$ (see Figures 7-9, Table 4).

Most of the parameters appeared well determined, their estimates having CV's on the order
of $20 \%$ or less. However, the estimates for $h$ and $a_{50}$ tended toward their lower boundaries of 0.30 and 1.0 , respectively.

## DISCUSSION

The base ASPM models were unable to reconcile the early increase in CPUE with the simultaneous increase in catch, as was also true of the ASPIC and FISHLAB formulations. This was to be expected inasmuch as the CPUE and catch observations increase simultanously, which cannot be satisfactorily interpreted by those models unless either recruitment or catchability is allowed to deviate fromthe model expectations (e.g., via allowance for process error). Inasmuch as this increase is early in the time series, allowing for process errors in recruitment is of little help (one cannot estimate variations in recruitment prior to the date when the data begins). However, as is evident in Figure 1 , allowing $q$ to vary as a random-walk process enabled the model to better reconcile the two trends. This reconciliation, however, comes at the expense of less precise parameter estimates. Moreover, all three models presented here were unable to provide meaningful estimates of either the steepness $h$ or the age of $50 \%$ selection $a_{50}$.

The estimate for $h$ tended toward the upper boundary of 0.95 in the composite models and the lower boundary or 0.3 in the fleet-specific model and seemingly minor changes in model structure or the order in which parameters were estimated could sometimes cause the parameter to swing to the lower boundary. The estimates for $a_{50}$ similarly tended to the boundaries. Clearly this behavior is an artifice of insufficient data, implying that more informative priors are needed. Failing that, there is probably little chance of reliably estimating process deviations in the state variables.

There are several areas in which this analysis may be improved. The steepness, growth, vulnerability, and natural mortality parameters cannot generally be estimated from catch and effort data alone. There may be some chance of estimating natural mortality by incorporation of tag-recapture data (as in Porch et al., 2001). Likewise, the vulnerability vector would become estimable by incorporating age-composition data even if it is not available for every year (as required by a VPA). The steepness parameter may also become estimable with an index of the abundance of the youngest age class. If such auxiliary information is not available, then expert guidance will be required to develop reasonable priors.

Priors for $h$ may be derived in principle from the meta-analyses of Myers et al. (1999) and Myers and Mertz (1998). Unfortunately, these analyses contain no information on Istiophorids. The closest phylogenetic groups in their analyses are a few scombrids, with $h$ values ranging between 0.38 and 0.92 , and a swordfish population with $h=0.88$. There is also very little information on the natural mortality and growth of Istiophorids. The value of $M$ was assumed to be low (around 0.10 ) based on the apparent longevity of the species, however empirical methods applied to striped marlin in the eastern pacific suggest much higher values between 0.4 and 1.3 (Hinton and Bayliff, 2002). The growth coefficients used here were borrowed from sailfish in the Gulf of California, but a possible alternative would be to use the coefficients estimated for striped marlin, which indicate a more rapid growth rate (see Hinton and Bayliff, 2002). Priors for the vulnerability coefficients, particularly $a_{50}$, maybe derived from the length frequency data for the various fleets assuming one of the growth curves is appropriate (at least for the younger ages). If this is done it might also be possible to allow different selectivity curves for each fleet.

Finally, it would be useful to explore appropriate weighting schemes for each of the indices
of abundance in the fleet-specific model. One possibility would be to use the weights already derived for the construction of the composite model. Another would be to use the estimates of the standard errors for each index, which would reflect inter-annual trends in samples sizes.

## ACKNOWLEDGMENTS

G. Scott provided the catch data by fleet.

Figure 1. Model fits to composite catch and CPUE series when q is assumed constant (left) or allowed to vary as a random walk (right).

## CONSTANT q

Figure 2. Estimated fishing mortality rates and selection curves for composite model when q is assumed constant (left) or allowed to vary as a random walk (right).

Figure 3. Estimated (modal) trends in spawning biomass from the composite model when q is assumed constant (top) or allowed to vary as a random walk (bottom).

Figure 4. Posterior distributions of steepness, maximum recruitment, current (1999) spawning biomass and current fishing mortality rate from the composite ASPM with constant $q$.

Figure 5. Model fits to fleet-specific catches.

Figure 6. Model fits to fleet-specific CPUE series.

Figure 7. Estimated trends in overall fishing mortality rate and selection curve for composite model.

Figure 8. Estimated (modal) trends in spawning biomass from the fleet-specific model.

Figure 9. Posterior distributions of steepness, maximum recruitment, current (1999) spawning biomass and current fishing mortality rate from the fleet-specific ASPM.
