# Tagging estimates of abundance at age for the northern region red drum stock. 

Noel Cadigan<br>CIE Expert<br>Fisheries and Oceans Canada<br>Lee Paramore<br>North Carolina Division of Marine Fisheries

#### Abstract

Trends in estimates of abundance derived from tagging estimates of fishing mortality rates ( F ) and independent estimates of catch-at-age were consistent with the general understanding of stock trends for northern red drum. However, we found that catch-curve estimates of F from tagging abundance-at-age estimates suggested lower F's overall than the tagging-F's themselves, although the trends in F's were similar. Until these discrepancies are resolved, it seems more prudent to use the tagging-F to assist in estimating a SCCA. Tagging-F's and their standard errors can be treated as direct inputs and fitted to SCCA model estimates of F. Fitting to $\log (F)$ may be reasonable but requires some investigation. Tagging-F's should only be compared with the appropriate F component in the SCCA.

## Introduction

Bacheler et al. (2008) gave estimates of fishing mortality (F) for North Carolina (NC) recreational and commercial fisheries based on recaptures from tagging experiments conducted during 1983-2006. These estimates were adjusted for tag loss and reporting rates and should be unbiased for the northern region red drum stock components in NC. It is felt that these components comprise the majority of this stock, and that the F estimates are indicative of the stock as a whole. These F's can be used to estimate stock abundance (at age which can be used in the statistical catch at age (SCCA) model as tuning indices with catchabilities (q's) fixed at one. Alternatively, the F's can be used directly to "fit" to SCCA model F. Pro's and Con's on these approaches are provided in the Discussion.

Bacheler et al. (2008) provided estimates of F for caught and kept fish, and also an $\mathrm{F}^{\prime}$ for fish caught and released, although the latter was not directly a source of mortality. Bacheler et al. (2008) assumed that $10 \%$ of released fish died, and they estimated an adjusted age-based annual fishing mortality rate,

$$
F_{a d j a y}=F_{a y}+0.1 F_{a y}^{\prime} .
$$

## Methods

The estimates of $F_{a d j, a y}$ and $F_{a y}$ can be used with an estimate of the kept catch at age ( $C_{a y}$ ) to estimate stock size,

$$
C_{a y}=\frac{F_{a y}\left(1-S_{a y}\right) \hat{N}_{a y}}{F_{a d j, a y}+M_{a y}}, S_{a y}=\exp \left(-F_{a d j, a y}-M_{a y}\right)
$$

In this equation, $S_{a y}$ is the annual survival fraction and $\left(1-S_{a y}\right) N_{a y}$ is the total deaths, of which the fraction $F_{a y} /\left(F_{a d j, a y}+M_{a y}\right)$ are due to kept catch. A more direct expression for the stock size estimate is

$$
\begin{equation*}
\hat{N}_{a y}=C_{a y} \frac{F_{a d j a y}+M_{a y}}{F_{a y}\left(1-S_{a y}\right)}, S_{a y}=\exp \left(-F_{a d j a y}-M_{a y}\right) \tag{1}
\end{equation*}
$$

Bacheler et al. (2008) assumed the following natural mortalities, $\mathrm{M}_{1}=0.3, \mathrm{M}_{2}=0.22, \mathrm{M}_{3}$ $=0.16$, and $\mathrm{M}_{4+}=0.10$. These are different from the values proposed for the SCCA assessment model. However, if $Z_{a y}=F_{a d j, a y}+M_{a y}$ is small then $1-S_{a y}=1-\exp \left(-Z_{a y}\right) \approx$ $Z_{a y}$ and

$$
\begin{equation*}
\hat{N}_{a y} \approx \frac{C_{a y}}{F_{a y}} . \tag{2}
\end{equation*}
$$

Hence, we expect the estimates of $N_{a y}$ to be fairly insensitive to the values used for $M_{a y}$, and we illustrate this in the Results. Note that the tagging estimates of $F$ may not be insensitive to the choice of $M$, but we could not evaluate this.

## Standard errors

Equation (2) also suggests a simple approximation for standard errors for $N$. Using the delta method it can be shown that

$$
\begin{align*}
& \operatorname{SE}(\hat{N}) \approx \hat{F}^{-1}\left\{\operatorname{Var}(C)+\hat{N}^{2} \times \operatorname{Var}(\hat{F})\right\}^{1 / 2} \\
& \approx \hat{N} \times C V(\hat{F})\left\{1+\frac{C V^{2}(C)}{C V^{2}(\hat{F})}\right\}^{1 / 2} . \tag{3}
\end{align*}
$$

where $C V$ is the coefficient of variation, $C V=S E /$ mean. If there is no error in catch then

$$
S E(\hat{N}) \approx \hat{N} \times C V(\hat{F}) .
$$

For simplicity, we did not include subscripts in the above equations, but in fact, tagging estimates of $F$ are available by year and for ages 1, 2, 3, and 4+. Bacheler et al. (2008) used a separable model for $F$, with selectivity estimated for three time periods $(p)$ :

$$
F_{a, y}=F_{\max . y} S_{a, y \in p} .
$$

$F_{m a x, y}$ is the fully recruited annual $F$, and $S_{a, p}$ is the age-selectivity for each period $p=1,2,3$. Bacheler et al. (2008) provided SE's for the $F_{\max , y}$ and $S_{a, p}$ estimates.
Covariances were not available to us. We used the following approximation for the SE of the $F_{a, y}$ estimates,

$$
\begin{aligned}
& \operatorname{SE}\left(\hat{F}_{a, y}\right) \approx\left\{\hat{F}_{\max , y}^{2} \operatorname{Var}\left(\hat{S}_{a, y \in p}\right)+\hat{S}_{a, y \in p}^{2} \operatorname{Var}\left(\hat{F}_{\max , y}\right)\right\}^{1 / 2}, \text { and } \\
& C V\left(\hat{F}_{a, y}\right) \approx\left\{C V^{2}\left(\hat{S}_{a, y \in p}\right)+C V^{2}\left(\hat{F}_{\max , y}\right)\right\}^{1 / 2} .
\end{aligned}
$$

If $\operatorname{COV}\left(F_{\max , y}, S_{a, p}\right)=0$ then the SE's and CV's approximations should be reasonable.

## Confidence intervals

An approximate (1-2 $\alpha$ ) $100 \%$ confidence interval for $N$ is

$$
\left(\hat{N}_{L}, \hat{N}_{U}\right)=\hat{N} \pm Z_{1-\alpha} S E(\hat{N})
$$

where $Z_{1-\alpha}$ is the 1- $\alpha$ quantile from a normal distribution. For example, if there is no error in the catch, i.e. $C V(C)=0$, and the CV for $F$ is $25 \%$ then a $95 \%$ confidence interval for $N$ would be $\pm 50 \%$ of the estimate. If there is no error in the catch then an alternative confidence interval method is the direct application of equation (2) to confidence intervals for F .

## Results

The estimates of $F$ and $F_{a d j}$ from Bacheler et al. (2008) are given in Table 1a and 1b and Figure 1. The results indicate that fishing mortality declined substantially in the early 1990's and varied little since then, except at age 2 in which F increased substantially in 2001 and 2002. Selectivites are shown in Figure 2 for the three periods. The overall trend is increasing selection of age 2 fish.

The assessment workshop concluded that the best estimates of $M$ were $0.20,0.13$, and 0.12 for ages $1-3$. We used 0.07 as an average value for age $4+\mathrm{M}$. Using these values and the catch data (commercial + recreational harvest) given in Table 2, population abundance was estimated using equation (1). These results are shown in Table 3 and Figure 3. This figure also illustrates the insensitivity of the population abundance estimates to the M values used in the tag-return model (Bacheler et al. 2008) versus those M values proposed for the SCCA assessment model.

Age specific population abundance estimates (Figure 4), while quite variable from year to year, generally suggested an increase in abundance since the early 1990's, especially at ages 2 and 3. Population abundance estimates for ages 1 to 3 will be provided as a potential tuning index in the SCCA assessment model. The confidence intervals in Figure 2 (and Table 4) were based on the assumption that $C V(C)=0$, which is clearly not correct. However, estimates of the CV for catch at age were not available. The CV's for F averaged $22 \%$ over all years and ages. If the catch CV's are about the same as the F CV's then equation (3) suggests that the confidence intervals should be increased by about $2^{1 / 2}=$ 1.4. If the catch CV is $50 \%$ then the confidence intervals should be increased 2.5 fold.

Stock size does not decrease with age for all cohorts in Table 3. This could be simply caused by estimation error; however, to investigate for systematic discrepancies we computed total mortality at ages 1 and 2 (i.e. catch curve Z's) and subtracted the AW M's to give total F implied by the tagging estimates of stock size (tagging-N). This should correspond closely with the tagging estimates of F (tagging-F). The Z values were more
variable since the early 1990's and, particularly for 1992-1994, the negative values indicate possible discrepancies between tagging F's and catches. This could be caused by, for example, bias in the F-selection pattern estimated from tagging, or bias in the age compositions of the catches. The tagging-N estimates of F were usually lower than the tagging-F's, especially at age 1 . Since the early 1990's tagging-N estimates of F have often been negative.

## Discussion

The tagging estimates of stock size (tagging-N's) were fairly noisy, with interannual variation that probably exceeds that in the stock. However, the trends in tagging-N's were consistent with the general understanding of stock trends, and the amount of noise was not excessive compared to other abundance indices available. Hence, the tagging-N's could be used to assist in estimating a SCCA. However, a problem is that catch-curve estimates of F from tagging-N's suggest lower fishing mortality overall than the taggingF's themselves, although the trends in F's were similar. There are several possible explanations for this. Until these discrepancies are resolved, it seems more prudent to use the tagging-F's to assist in estimating a SCCA. This is described in more detail below.

The assumption of $10 \%$ release mortality by Bacheler et al. (2008) is different from the value the Assessment Workshop concluded was most appropriate (i.e. 8\%). However, stock size estimates should be relatively insensitive to the value used for $\%$ release mortality, for the same reason they are relatively insensitive to the values used for M ; that is, $F_{a d j, a y}$ is not involved in equation (2).

More accurate methods such as the bootstrap or even the delta method based on the full covariance matrix for all tag-return model parameter estimators and equation (1) could be used to produce standard errors for tagging-N's and tagging-F's. However, these approaches are considerably more complex than the approaches we used, in part because the tagging model contains a fairly large number of parameters.

Incorporating tagging-N's into a stock assessment model such as SCCA is straightforward. Basically, they are treated the same as other indices, except the taggingN catchability $(\mathrm{Q})$ is fixed at one. This provides a valuable absolute scale to a stock assessment model. This scale can otherwise be difficult to fix if the time series is short or fishing mortalities are low, especially on older ages. A disadvantage of using tagging-N's is that they involve two sources of error: (1) the tagging-F's and (2) catch-at-age estimation. Accounting for the catch-at-age errors is not straightforward when these errors have to be estimated in the SCCA. Also, the catch data is already used in a SCCA, and using it a second time to produce tagging-N's may lead to false precision and other insidious problems that can occur if total catch estimates are biased in some years. This is analogous to the biases that can occur using a CPUE index to estimate a VPA when catch is under-estimated.

Using tagging-F's directly in a SCCA involves a more direct separation of information. Tagging-F's are not affected by measurement error in catch. SCCA attempts to account for catch estimation error, and providing independent estimates of F should improve SCCA in this regard. Using tagging-F's directly is simpler than using tagging-N's because tagging-F's and their standard errors are treated as direct inputs to the SCCA; however, SCCA software probably requires modification to use F inputs for estimation. Fitting to $\log (F)$ may be reasonable but requires some investigation. Bacheler et al. recreational release mortality. Care must be taken to compare tagging-F's with the appropriate F component in the SCCA.

## Tables and Figures

Figure 1. Adjusted total fishing mortality (points) and harvested fishing mortality (solid lines) from an age-dependent tag-return model. Dashed lines represent $95 \%$ confidence intervals for harvested fishing mortality.

Figure 2. Selectivity patterns in adjusted fishing mortality from an age-dependent tagreturn model. Age 2 is fully selected.

Figure 3. Population abundance (ages 1-4+ aggregated) estimates for the northern region red drum stock based on total harvest (commercial+recreational) and fishing mortality rates ( F ) estimated using an age-dependent tag-return model.

Figure 4. Population abundance estimates by age (ages 1-3) for the northern region red drum stock based on total harvest (commercial+recreational) and fishing mortality rates (F) estimated using an age-dependent tag-return model.

Figure 5. Catch curve estimates of Z (points) from tagging estimates of abundance at ages $1-3$. The solid lines are loess smooths of the Z estimates, and the dashed lines are $95 \%$ confidence intervals for smooth mean Z .

Figure 6. Catch curve estimates of F (points) from tagging estimates of abundance at ages $1-3$. The solid lines are loess smooths of the Z estimates, and the dashed lines are $95 \%$ confidence intervals for smooth mean $Z$. The blue lines show the estimates of F obtained directly from the age-based tagging model.
