# Standardization of commercial catch per unit effort of hogfish (Lachnolaimus maximus) from Florida Trip Ticket landings, 1994-2012. 

Wade Cooper<br>Florida Fish and Wildlife Conservation Commission<br>Fish and Wildlife Research Institute<br>100 8th Avenue SE, St. Petersburg, FL 33701

April 11, 2014

## Introduction

Indices of relative abundance were developed from the Florida Trip Ticket database for the two primary hogfish stocks within Florida: West Florida (WFL) and Southeast Florida including the Florida Keys (FLK/SEFL). These stock delineations are based on genetic analyses conducted on sampling from the WFL through North Carolina, suggesting little if any contemporaneous exchange between three distinct geographic groupings (WFL, FLK/SEFL, and N. Carolina; Seyoum et al. 2014).

## Methods

## Spatial and Temporal Extent

Given the distribution and stock structure of hogfish, two separate indices were constructed: one for the WFL and one for the FLK/SEFL. For the two Florida-centered stocks, only those landings from fishing areas and/or counties in the core distribution area were used: Franklin to Collier for the WFL stock, and Monroe to Indian River for the FLK/SEFL stock (Figure 1). Analyses were done for only years 1994-2012 when the gear code became a requirement on the trip tickets. Prior to 1994, all gear information from the trip ticket data should be considered as an estimate.

## Identification of Appropriate Surveys

To identify those commercial trips that were appropriate for catching hogfish, a cluster analysis was conducted to identify species often caught in association with hogfish. By identifying those trips that caught associated species but failed to catch hogfish, one can infer zero-catch trips that were appropriate to include in the analysis. While catching hogfish on hook and line is often considered rare, the total landings of hogfish using hook and line versus spear is of a comparable magnitude over the time frame when recording of gear used was required on the Florida Trip Tickets (1994-present; Tables 1 and 2). As such, both gear types were analyzed and indices of abundance were computed separately for the two for comparison. The SEDAR 6 review found that the use of hook and line data for hogfish was contentious due to lack of evidence for either recreational or commercial fisheries targeting hogfish with hook and line gear (Kingsley 2004). For this analysis, we use only those species objectively determined to be caught in association with hogfish for a given gear type in order to identify appropriate valid trips.

The data was filtered to remove all uncommon species that occurred on only a small proportion of the total trips and in particular those species that were rarely caught with hogfish. For both gear types, species caught on less than $1 \%$ of the total trips that caught hogfish were removed. Affinity propagation clustering (APC) was chosen to determine associated species, because it has been shown to perform well relative to other cluster techniques and does not require that the number of cluster be pre-specified (Frey and Dueck 2007). APC automatically chooses an optimal number of clusters in the dataset, thereby providing an objective criterion for which to group associated species. For the APC procedure, the Bray measure of similarity was used where data were converted to presence/absence of landings for each species and fishing trip. Once the associated species within the hogfish cluster were identified for each of the stocks and gear types, all trips on which these species were caught for a specific gear type were used as suitable valid trips in the subsequent analyses. The APC technique was done in R 3.0.1 (R Core Team 2013) using the apcluster package (Bodenhofer et al. 2011).

## Standardization Model

Standardized indices of abundance were calculated using a generalized linear modeling procedure that combined the analysis of the binomial information on presence/absence with the lognormal-distributed positive catch data (also known as two-part, hurdle, or zero-adjusted models, Zuur et al. 2009) as:

$$
\begin{equation*}
I_{y}=c_{y} p_{y} \tag{1}
\end{equation*}
$$

where $c_{y}$ are estimated annual mean CPUEs of non-zero catches modeled as lognormal distributions and $p_{y}$ are estimated annual mean probabilities of capture modeled as binomial distributions. The lognormal submodel considers only trips in which a hogfish was caught (i.e., non-zero catches). The binomial model considers all trips in which hogfish or associated species were caught. While other approaches exist to model zero-inflated data (i.e., Poisson and negative binomial distributions; zero-inflated models; Zuur et al. 2009), the two-part model used here is advantageous in that it provides inferences on both the presence-absence and abundance processes occurring within a population, and can easily accommodate different predictor variables for each sub-model in the statistical analysis.

To determine the most appropriate models, predictor variables were selected using a forward step-wise approach where each predictor was added to each submodel individually and the resulting reduction in deviance per degree of freedom (Dev/DF) analyzed. The factor causing the greatest reduction in Dev/DF was then added to the base model. Year was retained in all models to obtain an index of abundance over time. Other potential predictors included month,
depth fished, days fished, and region fished. The region fished variable applied only to the FLK/SEFL stock, where the Keys (Monroe county) and SEFL (Miami-Dade to Indian River counties) were keyed as separate regions to accommodate differences in reef habitat structure. We assume that there are no significant interaction terms with year in this model and consider only the main effects. Criteria for model inclusion also include a reduction in $\mathrm{Dev} / \mathrm{DF} \geq 0.5 \%$. This process was then repeated until no factor met criteria for model inclusion. Final yearspecific marginal means estimates and standard errors of the two sub-models were used to generate distributions of estimates for each sub-model from a Monte Carlo simulation (5000 Student's $t$ distributed realizations). The product of these distributions (eq. 1) provided an estimate of the median catch rate with year-specific variability. All analyses were done using R 3.0.1 (R Core Team 2013).

## Results and Discussion

## Species Prevalence on Commercial Fishing Trips

In order to ascertain valid trips, species often caught in association with hogfish were selected through multiple procedures. The first filtering step was to determine only those species caught on greater than $1 \%$ of the trips that caught a hogfish. This was done to eliminate any species that were rarely caught with hogfish in order to simplify the cluster analysis (see section below). For the WFL spear fishery, hogfish was recorded on 1,688 trip tickets from 1994-2012. In the filtered data, flounders were the most often caught species, with nearly three times more records than hogfish for the WFL spear fishery. Hogfish were recorded a similar number of times on trip tickets where hook and line was the primary gear type $(1,507)$, but this was a small fraction of the total hook and line trips conducted relative to the total number of spear fishing trips. A similar pattern was evident in the FLK/SEFL, where 6,068 trip tickets recorded hogfish when the primary gear was spear, and a similar magnitude of hook and line trips additionally recorded hogfish $(4,479)$. However, hogfish were the most often caught species on spear fishing trips, but were caught on only a small fraction of the total hook and line trips in the FLK/SEFL region (Table 3).

## Identification of Valid Commercial Trips

The APC technique was performed separately for the WFL gears and two stocks (hook-and-line versus spear; WFL versus FLK/SEFL stocks). For the WFS spear, the APC procedure selected 3 clusters from a total of 20 species. The species group in which hogfish clustered comprised the largest cluster with a total of twelve other species (Table 4), including the major groupers, snappers and grunts. For the WFL hook and line, the APC procedure selected 6 total clusters from a total of 35 species. The species group in which hogfish clustered was the $2^{\text {nd }}$ largest cluster with eight other species, and similarly included the groupers, grunts, and snappers as in the spear fishing trips (Table 4). For the FLK/SEFL spear, the APC procedure selected 5 clusters from a total of 22 species. The species group in which hogfish clustered was the $2^{\text {nd }}$ largest cluster with four other species of groupers and snappers (Table 4). And lastly, for the FLK/SEFL hook and line, the APC procedure selected 6 clusters from a total of 26 species. The species group in which hogfish clustered included four other species (Table 4). Figure 2 presents the frequencies of pounds of hogfish caught per trip for the two stocks and gear types after filtering for only those trips expected to encounter a hogfish (i.e., those trips either catching a hogfish or the associated species).

## Standardization Model

The results from the forward-stepwise model selection procedure are presented in Tables 5-12. The final predictor variables for each model component (binomial and positives model components, two stocks, and two gear types: eight total models) were those that explained greater than $0.5 \%$ of the residual deviance/DF in the deviance tables (percent.reduction column). Figures 3-10 present the diagnostics plots for each of the eight component models. In general, the models had relatively good fits to the positives data using a lognormal distribution (QQ plots are approximately normal).

The indices of abundance are presented in Tables 13-16 and Figures 11-14. Overall the indices were moderately variable with average coefficients of variation (CVs) of $18,23,5$, and $12 \%$ for the WFL spear, WFL hook-and-line, FLK/SEFL spear, and FLK/SEFL hook-and-line, respectively. The WFL spear CPUE increased from 1994 to 2012 in a stepwise fashion, with a first increase from 1999-2002, and a second increase from 2008-2012. The WFL hook-and-line CPUE did not demonstrate a similar pattern to the WFL spear CPUE, but instead was relatively stable across the entire time frame, marked with a temporary increase from 2000-2003, and a large temporarily increase in 2010 and 2011, both of which were followed by declines in abundance. The FLK/SEFL CPUE indices for both spear and hook and line were relatively stable across the time frame (1994-2012), marked with year to year fluctuations that generally did not correspond between the spear and hook and line CPUE trends. Given that hogfish are one of the primary species targeted on spear and rarely targeted on hook and line for commercial fisheries in the Florida stocks, the CPUE trends from the spear landings should be considered as a more accurate representation of the abundance than the hook and line landings data.
