

SEDAR 4 - DW - 01.  
Indices of abundance from commercial logbook data: U.S. South Atlantic stocks  
Data Workshop  
November 3-7, 2003  
Charleston, SC

### **Applicability of the Logbook Data for Assessments**

The question of the general usefulness of the logbook data for developing species indices was raised for group discussion. Two possible problems with using the data were discussed. First, the data do not allow obvious definition of effective effort. The fishery takes multiple species from a 'complex' that is not cleanly defined (in the sense of biology or targeting by the fishery). This makes it difficult to define fishing trips that caught none of a studied species, but had the potential to do so (i.e, effort but zero catch).

Second, the data are obtained from a directed fishery and therefore could contain problems associated with any fishery-dependent index. Change of the fishing efficiency of the fleet may have improved over time due to improved electronics (and how to address this possibility) was debated by the group. Associated with this question was the skill of fishermen, which may have changed over time. The possibility was raised that the best fishermen are now in the fishery and that fishermen of marginal skill were only present in the beginning of the data time series, particularly in the case of longline fishermen. This is based upon decreasing number of longline boats (in SC) and the expense of using that gear type. There was general agreement that change in skill of fishermen targeting deepwater species probably hasn't changed because marginally skilled fishermen never fished in deep water. Also of concern is the effect of changing market conditions and catchability. It was pointed out that there are problems associated with any abundance index and that very convincing evidence needs to be presented to not use the logbook data.

#### Recommendation:

**The group decision was to compute logbook indices, and to compare them to fishery independent indices (MARMAP).**

### **Available Data**

Commercial logbook data are detailed in SEDAR4-DW-30. Each record in the reef fish logbook data set is of a single species caught on a single trip. Variables recorded are listed and described in Appendix 1. The full data set was pared by excluding records that did not report area fished, number of lines (or sets), number of hooks, time fished, length of longline (if appropriate), or days at sea. This excluded approximately 7% of the records. The data set was then constrained to areas in the South Atlantic (24-35 degrees latitude). The logbook data contain some data that are clearly misreported or misrecorded; records with reported values that seem suspect are excluded. The variable

effort (hooks/line) is constrained to between 1 and 40; the variable numgear (number of lines) is constrained to between 1 and 10; the variable crew (number on boat) is constrained to less than 12. In addition, the hours fished must be greater than 0. Data were explored in terms of number of records. The group also recommended exploring the data by catch (weight).

The time series of the reef fish logbook data is short (1992-present), with only partial reporting in 1992. It was suggested in the discussion that the longline dataset might be expanded by converting some North Carolina longline data to logbook format. Those data begin in the mid-1980's. The group decided that addition of those data would be of limited use because of the small geographic coverage of the additional data.

There was discussion about the possibility that there may be a trend in the logbook longline data in which hooks per line and time fished have both increased over time in the data set. In addition, the data should be examined for a tendency in the handline data of the reported number of hooks per line to equal the number of lines fished.

There was much, and repeated, discussion by the group concerning the criteria/rationale for including particular species in the deepwater complex. There was agreement that speckled hind was not, biologically, a deepwater species and should be analyzed separately. This data set contains no depth information (see below) and, therefore, subsetting the speckled hind (or any of the species) data by depth cannot be accomplished with the reef fish logbook data.

Warsaw grouper (649 records), queen snapper (505 records) and misty grouper (342 records) may not have adequate data to construct indices of abundance from the reef fish logbook data set. Available data, number of records per year, by species is provided in Table 1. Co-occurrence of species by trip is listed in Table 2.

#### Recommendations:

- a. Examine the catch by year to identify data gaps in the available time series. Catch of speckled hind and warsaw grouper has been limited by regulation to one fish per vessel (and no sale) since 1994, most of the years represented in the logbook data. Explore methods for analyzing those species given this data limitation.
- b. Limit the species that are further analyzed to those that make significant contributions to landings, both economically and in terms of total pounds landed. Significant contribution needs to be defined. This was the recommendation accepted by the group.
- c. Defer further analysis of warsaw grouper and misty grouper due to lack of data.
- d. Efforts could be best focused on snowy grouper, blueline tilefish, or (golden) tilefish.**

### **Defining Catch**

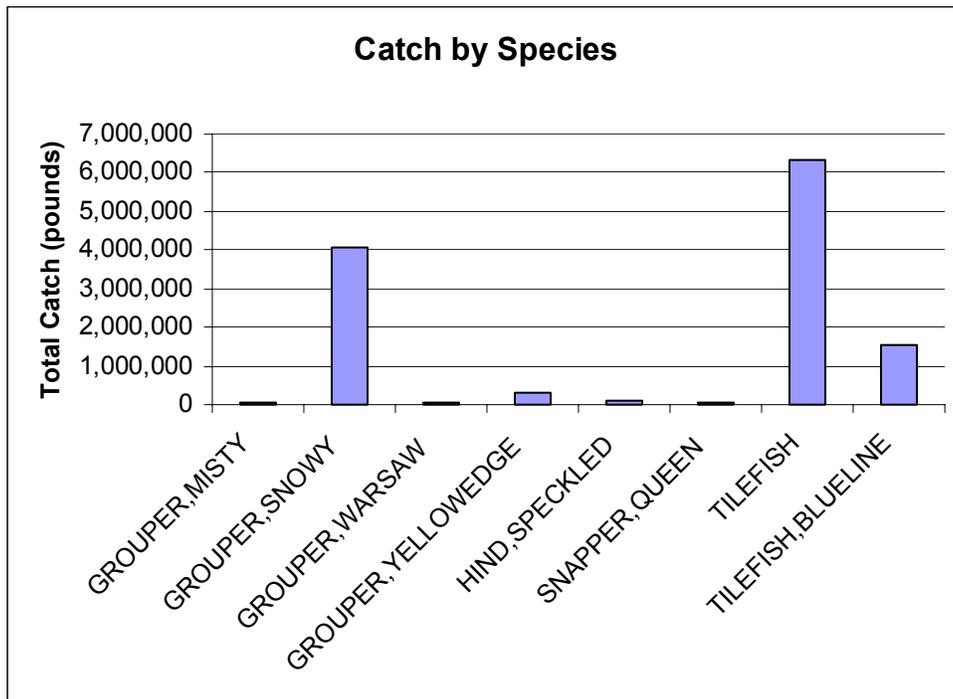

No depth information is available in this data set. Geographic resolution of fishing area is too coarse (one degree latitude by one degree longitude) to infer depth from reported area fished. Data are reported as total catch per species per trip with no age or size data available. The number of records is in Table 1 and the total catch by weight of each species is in Figure 1. Given the available logbook data, total pounds of

catch cannot be converted to number of fish caught. Similarly, changes in fishing patterns related to depth (shifting effort to different depths over years, seasons, geographic location, or when fishing different gear types) cannot be examined.

Recommendations:

- a. **The group decision was to utilize the data as they are and report results in weight.**
- b. Average weights from the TIP database may be used to convert weight from the logbook data to numbers of fish.
- c. Subset catch by gear type in the TIP database to determine gear use by depth.
- d. May use headboat data to get length/weight relationships of the deepwater species.

**Figure 1.** Total catch of the deepwater species complex reported in the commercial logbook program, 1992-2002.

## Defining effort

Defining effort from the reef fish logbook data set is not straightforward. Changes in the method of reporting hours fished for longline gear (hours per set changed to total hours fished) lead to an undecipherable mix of time data reported in the data set. Also, the definition of a trip in which effort was directed at catching one of the deepwater species is not obvious. Without an adequate definition of “trip” a reasonable estimation of effort cannot be made. Multiple suggestions were considered by the group and are listed below.

### Longline

1. The suggestion was made to accept all trips that use longlines. Regulations since 1992 (corresponding to the beginning of the reef fish logbook data time series) have limited longline gear to depths greater than 50 fathoms, therefore longline gear is fishing the deepwater complex. Longline trips targeting sharks should be excluded from the deepwater complex index of abundance analysis.

### Recommendations:

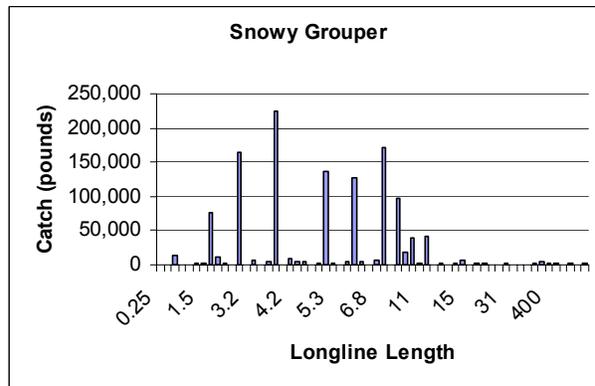

- a. Include all trips that use longlines except during shark open season. During shark open season, exclude shark trips by using species catch frequency data and eliminating trips when the deepwater species of interest comprise too small a percentage of the total catch (e.g. <10%) or, alternatively, include trips where sharks comprise a small percentage of the catch (e.g. <25%). Explore the data for reasonable delimiters.
- b. Include all trips with catch of the species of interest. The group recognized the problem of identifying trips with effort but no catch of the target species.
- c. Include all trips that use longlines except during shark open season. For periods of shark open season, use a species assemblage index to identify deepwater indicator species that can be used to identify trips targeting deepwater species. Other species (e.g. black belly rose fish) were suggested by the group as deepwater indicator species that might be used to identify deepwater trips.
- d. Examine longline gear configuration (hook density/longline and longline length and changes in those gear configurations over time) for differences between trips with predominantly shark and predominantly deepwater complex species in the catch. Use any gear configuration differences to identify trips targeting species in the deepwater complex. As was indicated in the group’s discussion, longline length and distance between hooks will vary by area fished. North Carolina gear

configurations typically have longer longlines with fewer hooks when golden tilefish are targeted, but shorter longlines with many hooks are used when snowy grouper are targeted. Blueline tilefish were a bycatch of the snowy grouper targeted trips in earlier years. Examine longline gear configuration by area for primarily snowy grouper and primarily tilefish trips. Explore the data to determine what constitutes primarily snowy grouper and primarily tilefish trips (snowy grouper > 50% of the catch for a trip).

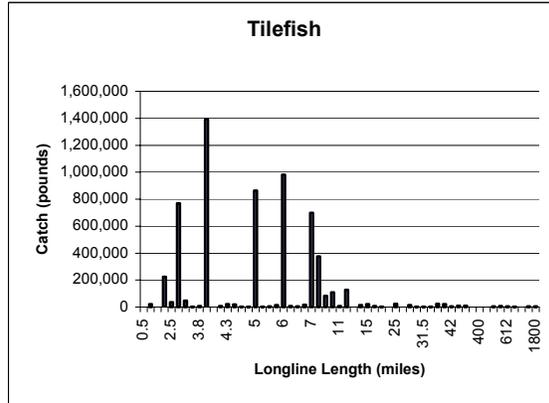

Initial Results:

Preliminary data exploration of gear configuration (no area delimitation) suggested no clear indication of targeted snowy grouper or tilefish by longline length or distance between hooks (Figure 2 A-D). Those analyses will be repeated by area.

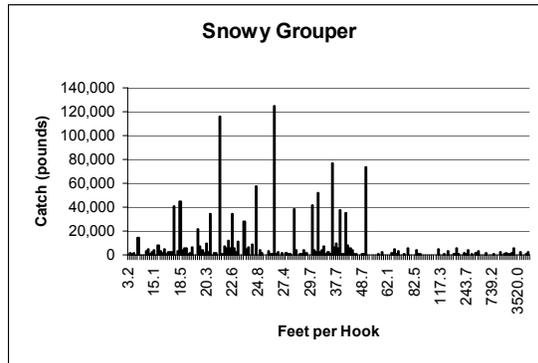

**Figure 2A.** Pounds of snowy grouper catch by longline length.

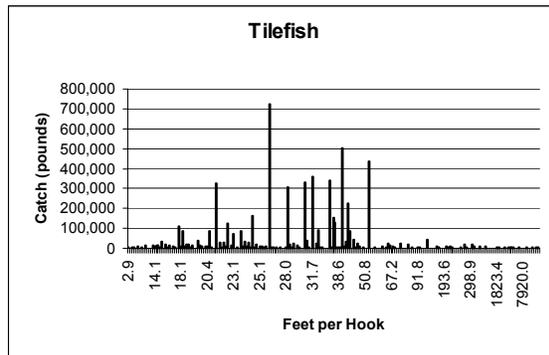

**Figure 2B.** Pounds of tilefish catch by longline length.

**Figure 2C.** Pounds of snowy grouper catch by distance between hooks.

**Figure 2D.** Pounds of tilefish catch by distance between hooks.

- e. Exclude shark trips by using species catch frequency data.
- f. For each deepwater species, identify a subset of vessels that land a high proportion of the catch of the species of interest. The gear configuration of those vessels can be examined over the time series.
- g. The group decision was to use an association statistic on all longline data to identify species assemblage (Appendix 2). The statistic was used to identify a list of possible species, from which species were selected based on biological knowledge (Table 3a,b).**

2. Hours fished cannot be determined unambiguously. Before 1993, longline hours fished was reported per set. Beginning in 1993, hours fished was to be reported as total hours fished. But old forms continued to be used, and some fishermen apparently continued to report hours fished per set even when using the new forms. This creates a problem in determining how hours fished was reported for many trips. This issue was examined prior to the DW, and an adequate solution was not found.

Recommendation:

**The group decision was to use hook days for longline indices because hook hours incorporates unreliable data. Preliminary indices of abundance using hook hours or hook days were very similar.**

## Handline

Handline data are less ambiguous for determining effort. Hook hours may be reliably calculated from these data. **However, for consistency with longline, the group preferred using hook-days.** As with the longline data, there remains the problem of determining what constitutes a deepwater handline trip in the logbook data set. Several methods were suggested during group discussion to address this problem.

### Recommendations:

- a. Select trips with a percentage of the total catch that was a species of interest to define targeted trips (e.g. >50% snowy grouper in the catch for a trip indicates a snowy grouper trip).
- b. Include all trips that caught species in the deepwater complex, but there is concern about which species were valid members of the deepwater complex.
- c. Constrain analysis to areas where target species was caught; exclude areas in bottom five percent of catch. Include trips from those areas that landed any of the eight species from the South Atlantic deepwater complex.
- d. Determine species composition for trips in which a minimum percentage (to be explored) of the catch consisted of deepwater species complex fish. Use the species composition of those trips to identify targeted trips.
- e. Determine targeted trips for each of the deepwater species by examining gear configuration (hooks/line and number of lines) by area from trips reporting the species of interest in the catch. The predominate gear configuration found in those trips is used to characterize deepwater trips and include all trips using that gear configuration. There was some discussion that this will not be particularly useful in defining directed effort for deepwater species.
- f. For each deepwater species, identify a subset of vessels that land a high proportion of the catch of the species of interest. The gear configuration of those vessels can be examined over the time series.
- g. **The group decision was to use an association statistic on all handline (including electric reel) data to identify species assemblage. The statistic was used to identify a list of possible species, from which species were selected based on biological knowledge (Table 4a,b).**

### Computing of indices of abundance

We used a delta-lognormal distribution (Lo et al., 1992, Can. J. Fish. Aquat. Sci., 49:2515-2526) to compute indices of abundance for snowy grouper and tilefish (Figure 3, 4). Factors were year, area, month, and gear. An empirical bootstrap will be used to obtain estimates of variance.

**Figure 3a: Snowy grouper index of abundance**

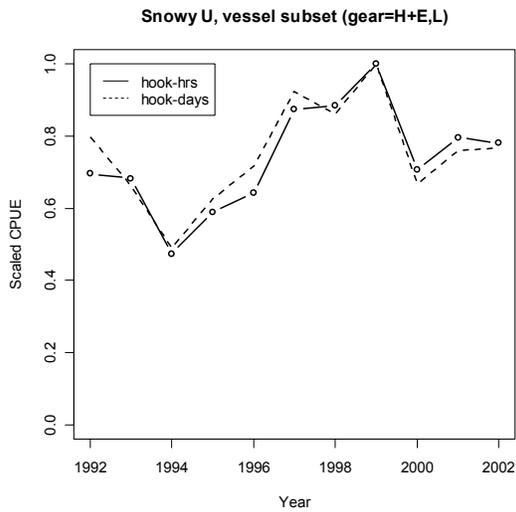

**Figure 3b: Tilefish index of abundance**

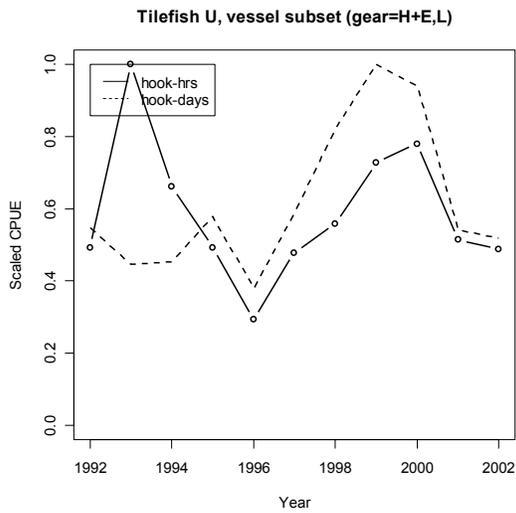

The indices were recomputed, but with a subset of vessels that were consistently in the fishery (Figure 4). Such vessels were determined as those that caught the studied species in at least 9 years of the 11-year period 1992-2002.

**Figure 4a: Snowy grouper index of abundance, from subset of vessels**

**Figure 4b: Tilefish index of abundance, from subset of vessels**

**Appendix 1** The commercial logbook data set contains the following variables (all are numeric unless otherwise noted):

**schedule:** this is a unique identifier for each fishing trip and is a character variable

**species:** a character variable. Codes for the south Atlantic deepwater complex, as defined for SEDAR4, are 1414 = snowy grouper, 4470 = tilefish, 4474 = blueline tilefish, 1415 = yellowedge grouper, 1411 = speckled hind, 3770 = queen snapper, 1420 = misty grouper, 4740 = warsaw grouper. Tilefish may also be listed under 4471, 4473, 4475, and 4477 (those codes are for different size classes), however, records with those species codes are not in the data set. See the excel file “Nmfsspec.xls” for codes of other species.

**gear:** a character variable, the gear type, multiple gear types may be used in a single trip, L = longline, H = handline, E = electric reels, B = bouy gear, GN = gill net, P = diver using power head gear, S = diver using spear gun, T = trap, TR = trolling

**area:** area fished, in the south Atlantic these codes have four digits- the first two are degrees of latitude and the second two are the degrees of longitude

**conversion:** conversion factor for calculating total pounds (totlbs) from gutted weight

**gutted:** gutted weight of catch for a particular species, trip, gear, and area

**whole:** whole weight of catch for a particular species, trip, gear, and area

**totlbs:** a derived variable that sums the gutted (with conversion factor) and whole weights, this is the total weight in pounds of the catch for a particular species, trip, gear, and area

**length:** length of longline (in miles) or gill net (in yards)

**mesh1 – mesh4:** mesh size of traps or nets

**numgear:** the amount of a gear used, number of lines (handlines, electric reels), number of sets (longlines), number of divers, number of traps, number of gill nets

**fished:** hours fished on a trip, this is problematic for longline data as discussed later

**effort:** like numgear, the data contained in this field depends upon gear type; number of hooks/line for handlines, electric reels, and trolling; number of hooks per longline for longlines; number of traps pulled for traps; depth of the net for gill nets, this field is blank for divers

**source:** a character variable, this identifies the database that the record was extracted from, sg = snapper grouper, grf = gulf reef fish, all records should have this source code

**tif\_no:** a character variable, trip identifier, not all records will have a tif\_no

**vesid:** a character variable, a unique identifier for each vessel

**started:** numeric (mmddyy8) variable, date the trip started

**landed:** numeric (mmddyy8) variable, date the vessel returned to port

**unload:** numeric (mmddyy8) variable, date the catch was unloaded

**received:** numeric (mmddyy8) variable, date the logbook form was received from the fisherman

**opened:** numeric (mmddy8) variable, date the logbook form was opened and given a schedule number  
**away:** number of days at sea, this value should equal (landed-started+1)  
**crew:** number of crew members, including the captain  
**dealer:** character variable, identifier for the dealer who bought the catch, in some cases there may be multiple dealers for a trip  
**state:** character variable, the state in which the catch was sold  
**county:** character variable, the county in which the catch was sold  
**area1 – area3:** areas fished, if the trip included catch from multiple areas, those areas will be listed here  
**trip\_ticke:** character variable, trip ticket number, a unique identifier for each trip not all trips have this identifier.

**Appendix 2** Association statistic for determining species caught (by gear) in connection with a studied species.

To define “effective effort” in a changing fishery, we must choose trips that could have taken the studied species. We define those trips as those that take a species commonly caught in connection with the studied species. The following equation was used to determine species caught alongside the studied species.

$$Assoc.Stat. \quad \frac{N(s, x)/N(s)}{N(x)/N}$$

$N(s)$  is the number of trips that caught the studied species;  $N(x)$  is the number of trips that caught species  $x$ ;  $N(s,x)$  is the number of trips that caught the studied species and species  $x$ ;  $N$  is the total number of trips. The statistic gives less weight to species that are more abundant in the overall catches, and more weight to species that tend to be caught in connection with the studied species. A potential problem with the statistic is that unreasonably high scores are given to species caught very infrequently, but alongside the studied species. Consequently, the group chose a minimum co-occurrence sample size of 100 (i.e.,  $N(s,x) > 100$ ). Species were then ranked by association statistic to create a list of possible inclusions, and the group selected species from the list based on biological knowledge.
