**ABSTRACT**

Red snapper (*Lutjanus campechanus*) is an economically valuable species utilized by recreational and commercial fishermen in the southeastern United States. During 2004, NOAA Fisheries and the Gulf of Mexico Fisheries Management Council will conduct data, assessment and review workshops to complete a stock assessment of red snapper in the U.S. Gulf of Mexico. Abundance or catch rate indices are useful for most stock assessment procedures. For this purpose, catch rate indices for red snapper observed by recreational anglers in the U.S. Gulf of Mexico were constructed using Marine Recreational Fisheries Statistics Survey (MRFSS) and Texas Parks and Wildlife Department (TPWD) data sets. Delta-Poisson indices were constructed using two different approaches. The indices are quite similar. Both demonstrate the influence of strong year classes, and suggest higher catch rates of red snapper after 1990.

**INTRODUCTION**

Red snapper is a valuable resource in the U.S. Gulf of Mexico. During 1998-2002, about 9 million pounds were landed annually within the U.S. Gulf of Mexico by commercial and recreational fishermen. While the value of the recreational fishery is difficult to quantify, it is estimated that Gulf wide, approximately 264,000 individual recreational trips target red snapper annually (Holiman, 1999). The commercial catch was valued at approximately \$10 million annually.

Red snapper are found in the western Atlantic Ocean and Gulf of Mexico, from Massachusetts to the Bay of Campeche, but are infrequent north of Cape Hatteras, NC (Hoese and Moore, 1998). Adults are common in submarine gullies and depressions, and over coral reefs, rock outcrops and gravel bottoms. They are most commonly found at depths of 40-110 meters<sup>1</sup>. Typically, red snapper reach a size of approximately 1000 mm TL, and weights up to

---

<sup>1</sup> NOAA Fisheries, Southeast Fisheries Science Center, Panama City Laboratory.

9.2 kg (Wilson and Nieland, 2001). Although ages in excess of 50 years have been observed, the vast majority of red snapper landed in the Gulf of Mexico are less than 15 years old (Wilson and Nieland, 2001).

In 2004, NOAA Fisheries personnel, Gulf of Mexico Fisheries Management Council (GMFMC) members, scientific experts, fishermen and other interested parties will participate in a series of workshops (Southeast Data Assessment and Review; SEDAR) to determine the status of the Gulf population of red snapper. To accomplish this objective, catch rate indices (or other abundance indices) are useful. This document describes the construction of alternative catch rate indices for the recreational fishery for red snapper in the U.S. Gulf of Mexico. These indices were created for formal consideration during the April 2004 SEDAR data workshop in New Orleans, LA. They are appropriate for use during stock assessment modeling procedures.

## METHODS

### Data Sources

NOAA Fisheries initiated the Marine Recreational Fisheries Statistics Survey (MRFSS) in 1979 in order to obtain standardized estimates of participation, effort, and catch by recreational fishermen in U.S. marine waters. MRFSS data is collected using two approaches: a telephone survey of households in coastal counties, and dockside interviews of fishermen (intercept survey). MRFSS intercept data was used for the construction of catch rate indices.

MRFSS intercept survey sampling coverage has varied over the time series. Initially, the survey covered shore fishing, as well as charter boat (CB), headboat (HB) and private boat (PB) fishing modes in all Gulf States. During 1982-1984, MRFSS discontinued sampling boat modes in Texas. This program was turned over to the Texas Park and Wildlife Department (TPWD) which began sampling Texas boat modes in the summer of 1983. Headboat sampling Gulf wide was transferred to the NOAA Fisheries Headboat Survey (HBS) program in 1986. TPWD continued to survey bay headboats until July, 1991. The MRFSS program no longer recommends the use of data collected during 1979 and 1980 or wave 4 of 1981-1985. Therefore, these data were not included during the construction of catch rate indices<sup>2</sup>.

**Index 1:** Two catch rate indices were constructed. The first (hereafter referred to as Index 1) was intended to replicate the recreational index used during the most recent red snapper assessment (Schirripa and Legault, 1999) using a similar technique. This index was constructed using MRFSS intercept data from 1981-2003 and TPWD catch and effort data from 1983-1989. TPWD data was not included after 1989 because strict minimum size and bag limits were mandated in 1990 (Table 1). Unlike MRFSS data which includes fish landed and observed by the interviewer (A), dead fish not observed by the interviewer (B1; e.g., unavailable, filleted, used for bait, discarded dead at sea) and fish released alive (B2), TPWD data only records fish observed by the interviewer (A; presumably most landed fish were available for observation). TPWD data is not appropriate to combine with MRFSS intercept data after the 1990 regulations because the proportion of red snapper discarded by the recreational fishery may have increased significantly.

<sup>2</sup> Patty Phares. Personal communication. NOAA Fisheries, Southeast Fisheries Science Center. Miami Laboratory.

All HB, CB and PB trips that fished in “oceanic” areas using hook and line gear were included in the dataset used to construct the first standardized index of abundance. Shore mode and inshore fishing trips were excluded as they very seldom land red snapper. Table 2 summarizes the interviewed trips by year, state and fishing mode.

**Index 2:** A second index (hereafter referred to as Index 2) was constructed using only MRFSS intercept data. Like the previous approach, all HB, CB and PB trips that fished in “oceanic” areas using hook and line gear were initially included. These trips were examined to identify a list of species associated with red snapper in two Gulf regions, east (FL, AL, MS) and west (LA, TX). Then, trips were excluded if they did not catch a least one red snapper, or a species associate. The final data set was intended to exclude trips with a low probability of observing red snapper due to unrecorded covariates such as depth and location of fishing, bait choice, bottom type and gear configuration. Table 3 is a summary of the interviewed trips identified for index 2 by year, state and fishing mode. Texas was excluded from the analysis due to insufficient sampling (n=59).

The two sets of species associates (east and west) were identified using an association statistic proposed by Heinemann<sup>3</sup>. The association statistic was calculated for each species (species x) reported by >50 trips during 1981-2003 (Eq. 1).

$$\text{Association Statistic} = \frac{\#Trips \text{ with Red Snapper and Species } X}{\#Trips \text{ with Red Snapper}} \bigg/ \frac{\#Trips \text{ with Species } X}{\#Total \text{ Trips}} \quad (1)$$

The association statistic does not provide an objective critical value at which to include or exclude a species. A value of 1.0 implies that a given species co-occurs with red snapper exactly as often as random chance would predict. Values >1.0 indicate that a species co-occurs more often with red snapper than expected, and values <1.0 indicate that a given species co-occurs with red snapper less often than expected. For this analysis, a species was assumed to be associated with red snapper if its association statistic was  $\geq 3.0$ .

## Index Development

**Index 1:** Like the previous red snapper recreational index (Schirripa and Legault, 1999), the factors YEAR, MONTH, MODE (PB, HB, CB) and STATE (FL, AL, MS, LA, TX) were considered as possible influences on the probability of catching a red snapper, and the catch rates on positive trips.

**Index 2:** This analysis examined the influence of the factors YEAR, SEASON (Dec-Feb, Mar-May, Jun-Aug and Sep-Nov), MODE (PB, HB, CB) and STATE (FL, AL, MS, LA) on the probability of catching a red snapper, and the catch rates on positive trips.

A delta-Poisson approach (Lo et al., 1992) was used to develop the standardized indices of abundance. This method combines separate generalized linear modeling (GLM) analyses of

---

<sup>3</sup> Heinemann, Dennis. The Ocean Conservancy, 1725 DeSales Street, Suite 600, Washington, D.C. 20036

the probability of success<sup>4</sup> (trips that observed red snapper) and the catch on successful trips<sup>5</sup> to construct a single standardized index of abundance. Parameterization of each model was accomplished using a GLM procedure (GENMOD; Version 8.02 of the SAS System for Windows © 2000. SAS Institute Inc. Cary, NC, USA). For the Poisson models, the response variable, catch, was calculated:

$$\text{Catch} = A + B1 + B2 \quad (2)$$

where A = fish observed, B1 = dead fish not observed and B2 = fish released alive. B1 and B2 catch, as well as effort (angler hours) were corrected for non-interviewed fishermen. When necessary, catch was rounded to the nearest whole number.

A forward stepwise approach was used during the construction of each GLM. First, a null model was fit. These results reflect the distribution of the nominal data. Next each potential factor was added to the null model individually, and the resulting reduction (%RED) in deviance per degree of freedom (DEV/DF) was examined. The factor that caused the greatest reduction in deviance per degree of freedom was added to the base model if the factor was significant based upon a Chi-Square test ( $\text{PROBCHISQ} \leq 0.05$ ), and the reduction in deviance per degree of freedom was  $\geq 1\%$ . This model then became the base model, and the process was repeated, adding factors and two-way interaction terms individually until no factor or interaction met the criteria for incorporation into the final model. Higher order interaction terms were not examined.

The final delta-Poisson model was fit using a SAS macro, GLIMMIX (glmm800MaOB.sas: Russ Wolfinger, SAS Institute). All factors were modeled as fixed effects except two-way interaction terms containing YEAR (e.g. YEAR\*STATE). These were modeled as random effects. To facilitate visual comparison, a relative index and relative nominal CPUE series were calculated by dividing each value in the series by the mean value of the series.

## RESULTS AND DISCUSSION

### Index 1

This index was intended to replicate and update the 1999 red snapper recreational index reported by Schirripa and Legault (1999). However, Index 1 deviates from a strict replication in that it was constructed using a binomial error structure for the analysis of proportion successful trips and a Poisson error structure for the analysis of the catch rates on successful trips. Also, TPWD after 1989 was excluded.

The stepwise construction of the binomial model on success is summarized in Table 4. The final model was:

$$\text{SUCCESS} = \text{MODE} + \text{STATE} + \text{YEAR} + \text{MONTH} + \text{MONTH} * \text{STATE} + \text{YEAR} * \text{STATE}$$

---

<sup>4</sup> Type-3 model, error = binomial, link = logit, response variable = success (where success = 1 if red snapper catch > 0, else success = 0)

<sup>5</sup> Type-3 model, error = Poisson, link = log, offset = log (angler hours), response variable = catch (where catch  $\neq$  0).

Although the interaction terms YEAR\*MONTH and MODE\*STATE were significant, and reduced the DEV/DF by  $\geq 1\%$ , the validity of models containing these terms was questionable (negative of Hessian not positive definite). Therefore, these interaction terms were excluded.

Annual variations in the proportion of positive trips are summarized in Figure 1. The probable influence of a large year class is evident in 1983, but subsequently, the proportion of positive trips returned to about the 1981-1982 level during 1985-1996. An increase in the proportion of positive trips has occurred recently, from 1997-2003. Diagnostic plots were examined to evaluate the fit of the binomial model. The distributions of the chi-square residuals by the factors MODE, STATE, YEAR and MONTH (Fig 2A-D) indicate an acceptable fit. In general, the residuals are distributed evenly above and below zero, and show no trend in variance with year.

The stepwise construction of the Poisson model on catch during successful trips is summarized in Table 5. The final model was:

$$\text{CATCH} = \text{YEAR} + \text{STATE} + \text{MODE} + \text{MONTH} + \text{YEAR*MONTH} + \text{YEAR*STATE} + \text{YEAR*MODE}$$

The annual trend in nominal CPUE is shown in Figure 3. The trend in nominal CPUE is quite similar to the trend in proportion positive trips. A large increase occurred in 1983, but CPUE returned to low values in 1984. Higher CPUEs occur in 1991 and 1992 and from 1997 to the present. Diagnostic plots were examined to assess the fit of the Poisson model to catch on positive trips. The distributions of the residuals by the factors MODE, STATE, YEAR and MONTH (Fig 4A-D) indicate over-dispersion. (The Poisson model assumes that Mean = Variance. This assumption is violated.)

The delta-Poisson abundance index, with 95% confidence intervals, and the nominal CPUE series are shown in Figure 5. To facilitate visual comparison, each series was scaled to its respective mean. The index statistics can be found in Table 6. The standardized abundance index is roughly similar to the nominal CPUE series. Index 1 indicates that, for the recreational fishery, catch rates were lowest during 1984-1990. Since then, the catch rates have improved considerably. This result suggests the population of red snapper has increased since 1990.

## Index 2

Index 2 was constructed using a different approach which, in addition to excluding shore modes and inshore fishing, also excluded trips that did not catch red snapper, or a species associated with red snapper. Lists of the species associates identified for the eastern and western Gulf, and their association statistics are summarized in Tables 7 and 8.

The stepwise construction of the binomial model on success is summarized in Table 9. The final model was:

$$\text{SUCCESS} = \text{STATE} + \text{MODE} + \text{YEAR} + \text{SEASON} + \text{SEASON*STATE}$$

Although the interaction terms MODE\*STATE, YEAR\*STATE and YEAR\*SEASON were significant, and reduced the DEV/DF by  $\geq 1\%$ , the validity of models containing these terms was

questionable (negative of Hessian not positive definite). Therefore, these interaction terms were excluded.

Annual variations in the proportion of positive trips are shown in Figure 6. In this case, the proportion of positive trips fluctuates around 45% until 1997 when it increases to ~60%. Then, the proportion of positive trips remains between 60% and 65% throughout the remainder of the time series. Diagnostic plots were examined to evaluate the fit of the binomial model. The distributions of the chi-square residuals by the factors MODE, STATE, YEAR and MONTH (Fig 7A-D) indicate an acceptable fit. In general, the residuals are distributed evenly above and below zero, and show no trend in variance with year.

The stepwise construction of the Poisson model on catch during positive trips is summarized in Table 10. The final model was:

$$\text{CATCH} = \text{YEAR} + \text{STATE} + \text{MODE} + \text{SEASON} + \text{YEAR} * \text{STATE} + \text{YEAR} * \text{SEASON} + \text{YEAR} * \text{MODE}$$

The annual trend in nominal CPUE is shown in Figure 8. The trend in nominal CPUE is quite similar to the trend in proportion positive trips. The lowest values occur during the early part of the time series. A large increase in CPUE occurred in 1990, and CPUE remained high throughout the remainder of the time series. Diagnostic plots were examined to assess the fit of the Poisson model to catch on positive trips. The distributions of the residuals by the factors MODE, STATE, YEAR and MONTH (Fig 9A-D) indicate over-dispersion.

Index 2 results are summarized in Figure 10 and Table 11. The standardized abundance index is quite similar to the nominal CPUE series. Like Index 1, Index 2 results indicate an increase in the population of red snapper since 1990. Figure 11 summarizes all the indices discussed in this manuscript, including the index used in the previous assessment (Schirripa and Legault, 1999). Although the annual index values are not identical, all the indices have the same overall trend, and all agree that the population red snapper increased after 1990.
