SEDAR 72 Gulf of Mexico Gag
December 7, 2020
revised June 30, 2021

## Background

The Marine Recreational Information Program (MRIP) has provided vital statistics on recreational fishing effort and catch in the eastern U.S. Gulf of Mexico since 1981. In order to remain useful for regional stock assessments, the time-series has undergone several calibrations to account for the effects of survey design improvements in more recent years. Stock assessments require long-term time-series of landings and discards on an annual scale that are measured consistently through time. Regional stock assessments provide biological reference points, which are used by fisheries managers to set sustainable limits for fishery removals. For federally managed reef fish stocks, recreational fishing seasons and other restrictions are set with the goal of keeping fishery removals below a threshold limit, and precise and timely estimates are needed to track landings against prescribed annual catch limits (ACLs) and ensure overfishing is not occurring.

In response to a region-wide need for more precise and timely estimates of recreational catch, Florida's Gulf Reef Fish Survey (GRFS) was developed in collaboration with NOAA Fisheries alongside similar efforts in other states. The GRFS was implemented in May 2015, and is currently used by the Florida Fish and Wildlife Conservation Commission (FWC) to manage recreational harvest levels for Red Snapper off the Gulf coast of the state and track landings against a state-specific allocation of the Gulf-wide ACL. Detailed methodology of the GRFS is described in detail in Appendix A, Results from the first year of an exempted fishing permit (18-SERO-01) for state management of Red Snapper recreational harvest in Florida. Beginning July 1, 2020, the Gulf Reef Fish Survey was expanded statewide in Florida and is now known as the State Reef Fish Survey (SRFS). The GRFS runs concurrent with the MRIP survey in Florida and produces estimates that are consistently lower. A method is needed to convert catch advice derived from a stock assessment to the same currency as the GRFS. Historic MRIP estimates converted to the GRFS currency are also needed to integrate multiple MRIP-calibrated timeseries from different surveys conducted in each state in order to provide one consistent set of estimates for use in regional assessments (NOAA Fisheries, 2019). A historic time-series converted to GRFS currency may also be useful on its own for assessing stocks in the eastern Gulf that occur primarily off the west coast of Florida (e.g. gag, red grouper).

## Objectives

The objectives are to develop species-specific conversion factors that may be applied to annual, fully calibrated MRIP estimates, and produce a historic time series in the same currency as the GRFS. To accomplish this, an appropriate ratio with associated variance is developed from estimated landings (in numbers and pounds) and releases (numbers) for six species in both state and federal waters derived from two surveys conducted during recent overlapping years: the Florida Gulf Reef Fish Survey (GRFS) and the Marine Recreational Information Program
(MRIP). The estimated ratios and associated uncertainty are used to convert the historical MRIP time series to a common currency with GRFS.

## Methods

This analysis used estimates of total landings (numbers and pounds of fish) and releases (numbers) derived from the GRFS and the MRIP from May 2015 through December 2019 when the two surveys overlapped. The two surveys use separate methods to calculate fishing effort (angler trips); however, catch estimates from the two surveys are not completely independent. To estimate catch-per-unit-effort (CPUE), the MRIP survey uses data from the Access Point Angler Intercept Survey (APAIS), whereas the GRFS uses a combination of data from the APAIS and supplemental reef fish angler intercepts. Assignments for both intercept surveys are drawn together so that sample weights are compatible (Foster, 2018).

Recreational harvest seasons for reef fishes off the Gulf coast of Florida have varied widely over recent years and across state and federal jurisdictions. For example, recreational harvest seasons for Red Snapper in the Gulf historically spanned 6-12 months, but during years that the GRFS and MRIP surveys overlap seasons have only been open for a limited number of weeks or days. In the past, season lengths were also consistent in state waters and federal jurisdictions, whereas in some recent years harvest has remained open longer in state waters. Rather than apply calibrations at a fine scale back in time (e.g. by month or area fished), it is more appropriate to quantify the overall differences between GRFS and FCAL estimates across the variable years and waves over which the two surveys overlap so that a single calibration factor may be applied to annual FCAL estimates back in time.

Estimates for state and federal waters were derived for six species: Gag, Gray Triggerfish, Greater Amberjack, Red Grouper, Red Snapper, and Vermilion Snapper. To assess overall differences between GRFS and FCAL estimates, the estimates $(\hat{E})$ and variances $(\hat{V})$ for each estimation method ( $m$ : GRFS, FCAL) were summed across years ( $y$ ), two-month waves ( $w$ ), and areas fished ( $a$ : federal or state waters) for each combination of species $(s)$ and variable ( $v$ : number landed, pounds landed, number released) [1, 2].

$$
\begin{aligned}
\widehat{E}_{m, s, v} & =\sum_{m, s, v} \widehat{E}_{y, w, a, m, s, v}[1] \\
\hat{V}\left(\widehat{E}_{m, s, v}\right) & =\sum_{m, s, v} \hat{V}\left(\widehat{E}_{y, w, a, m, s, v}\right)[2]
\end{aligned}
$$

This resulted in 18 pairs of GRFS and FCAL sums (3 variables x 6 species; Table 1). For each of the 18 paired sums, the ratio was calculated as the total GRFS estimate divided by total FCAL estimate [3].

$$
\hat{R}_{s, v}=\frac{\widehat{E}_{G R F S, s, v}}{\widehat{E}_{F C A L, s, v}}[3]
$$

The delta method was used to approximate the variance of the ratios $\left(\hat{V}\left(\hat{R}_{s, v}\right)\right.$ ), and incorporates error associated with both the numerator (GRFS estimates) and denominator (FCAL estimates). The R statistical software package 'msm' (R Core Team 2018; Jackson 2011) was used to carry out variance calculations. Although GRFS and MRIP estimates are derived from survey data that are not completely independent, the strength of correlation between estimates from the two surveys is unknown. To evaluate the influence of correlation ( $\rho$ ), we approximated variances at three levels: $\rho=0, \rho=0.5$, and $\rho=0.9$. No correlation ( $\rho=0$ ) represents the most conservative approximation of variance if correlation between the two survey estimates is ignored. An upper limit of $90 \%$ correlation ( $\rho=0.9$ ) was selected based on linear regressions, and $50 \%(\rho=0.5)$ assumes at least some correlation between estimates is explained by shared data that both surveys have in common.

Historic estimates were converted to GRFS currency by multiplying the annual FCAL estimate for each year, species, and variable type (number landed, pounds landed, number released) [4] with the corresponding ratio [3]:

$$
\hat{E}_{G R F S-h i n d, y, s, v}=\hat{R}_{s, v} \hat{E}_{F C A L, y, s, v}[4]
$$

Variance was once again approximated using the delta method. No additional correlation was included in this calculation.

Some stock assessments require the Florida Keys data to be either included or excluded depending on the species being assessed. Because the GRFS provides catch estimates for Florida's Gulf waters excluding the Keys while MRIP provides estimates for west Florida that includes the Keys or excludes the Keys, we calculated a ratio calibration factor for both GRFS/FCAL with Keys and GRFS/FCAL without Keys, and provide the hindcast FCAL estimates in GRFS currency that both include and exclude the Keys. Depending on specific stock assessment needs, i.e. including or excluding the Keys, the appropriate calibrated time series can be utilized.

Because gag were mis-identified as black grouper in the early years of the historic time series, i.e., $1982-1989$, we calculated a simple ratio to characterize the difference between the FCAL landings estimates and the black grouper-adjusted FCAL landings estimates, e.g., black-grouper adjusted FCAL/FCAL), and then applied this ratio to the corresponding GRFS currency time
series. A simple ratio was utilized because we did not have the required error associated with the estimates to utilize the corrected data set in the delta method described above.

## Findings and Conclusions

For the years in which the GRFS and MRIP overlap, annual Gag estimates derived from GRFS and FCAL and associated variances, observed ratios of summed GRFS to FCAL estimates and approximated variance for each level of correlation are provided in Table 1 (excluding the Keys). For Gag landings in pounds excluding the Keys, the ratio was 0.42 and the PSE of the ratio was 7.0 at $50 \%$ correlation.

The original FCAL time-series excluding the Keys, and corresponding FCAL estimates converted to GRFS currency with $50 \%$ correlation for Gag are shown in Figure 1. The degree of correlation assumed for the ratio variance calculation did not have a large influence on overall PSE's for calibrated estimates. When FCAL estimates for Gag were converted to GRFS currency, the PSEs differed by at most 6.6, between the lowest and highest levels of correlation assumed for the ratio calibration factor respectively, for estimates excluding the Keys. Under the varied assumptions of correlation, differences in PSEs for FCAL estimates calibrated to GRFS currency ranged from $1.7-6.6$ for Gag landings in number of fish, $0.9-3.9$ for landings in pounds, and $0.4-4.5$ for releases in number of fish. Given that some dependence between the two surveys is known and the degree of correlation does not have a large impact on PSEs for final calibrated estimates, the ratio variance that assumes at least $50 \%$ correlation is recommended for use (Table 2). Landings estimates from the original FCAL time series excluding the Keys, the black grouper-adjusted FCAL times series, FCAL estimates converted to GRFS currency (from Table 2), the black grouper adjustment ratio for 1982-1989, and the final black-grouper-adjusted estimates in GRFS currency are given in Table 3.

The purpose of this report was to establish an accepted method for producing converted FCAL estimates for fisheries management and potential use in future stock assessments. Results presented in this report include data collected over 56 months (through December 2019). The two surveys continue to run concurrently in Florida. Since this analysis was conducted, estimates for 2020 have become available. Once this method is established, calibration factors that include the complete available time-series of overlapping data may be routinely updated and shared as needed.

Figure 1. Gag hindcast estimates excluding the Keys from: GRFS, FCAL, and FCAL converted to GRFS currency (GRFS/FCAL CALIBRATION). The $95 \%$ confidence intervals were calculated assuming 50\% correlation between the two survey estimates.

Table 3. Historic (MRIP - FCAL) estimates, black grouper-adjusted estimates (MRIP-BG Adjusted), estimates converted to GRFS currency (GRFS), black grouper adjustment ratio calculated as MRIP-BG Adjusted divided by MRIP-FCAL estimates, and estimates converted to GRFS currency with black grouper correction (BG-Adjusted GRFS) excluding the Keys for Gag. Associated percent standard errors (PSE) are given for the $50 \%$ correlation used to calculate variance for the calibration factor (ratio of GRFS to FCAL). The black grouper adjusted MRIP estimates were provided without error estimates, hence PSE and standard error calculations are missing for those estimates as well as the black grouper adjustment ratio, and the final black grouper adjusted GRFS estimates.
